Dynamical mean-field theory (DMFT) has been employed in conjunction with density functional theory (DFT + DMFT) to investigate the metal-insulator transition (MIT) of strongly correlated 3d electrons due to quantum confinement. We shed light on the microscopic mechanism of the MIT and previously reported anomalous subband mass enhancement, both of which arise as a direct consequence of the quantization of V *xz*(*yz*) states in the SrVO₃ layers. We therefore show that quantum confinement can sensitively tune the strength of electron correlations, leading the way to applying such approaches in other correlated materials.

DOI: [10.1103/PhysRevResearch.3.023149](https://doi.org/10.1103/PhysRevResearch.3.023149)

I. INTRODUCTION

In strongly correlated quantum materials, the interaction energy between electrons is comparable with their kinetic energy, leading to many-body behavior and the emergence of qualitatively new phenomena [1]. For example, transition metal oxides host properties as diverse as colossal magnetoresistance, high-temperature superconductivity, and Mott insulating phases, each of which have huge potential for future device and technology applications [2,3]. More recently, substantial advances in the quality and control of layer-by-layer growth methods have facilitated designed transition metal oxide heterostructures and superlattices (SLs), often focusing on emergence at interfaces and/or surfaces [4]. Here, we show that correlated electronic behavior may be delicately tuned by quantum confinement, which narrows the effective bandwidth of the correlated quantum well (QW) subbands and establishes another means to tune physical properties to suit applications. We illustrate this by driving the prototypical correlated metal SrVO₃ through a metal-insulator transition (MIT) to a Mott insulating phase, in excellent quantitative agreement with the experimental spectral function extracted from recent spectroscopic measurements [5].

In the bulk, SrVO₃ is a well-characterized correlated metal [6]. Sharp 3d quasiparticle (QP) bands at low excitation energies lead to a well-defined Fermi surface [7], while localized states form incoherent Hubbard sidebands at an energy scale comparable with the Coulomb repulsion parameter *U* [8,9]. Together, these yield the familiar three-peaked spectral function [3,10]. While density functional theory (DFT) often adequately describes QP states (once renormalization is ac-

counted for), it is not capable of capturing the many-body behavior, e.g., Hubbard sidebands are completely absent. Dynamical mean-field theory (DMFT), on the other hand, can describe all of the onsite local correlations [3,10] and has been well-tested on SrVO₃ with very good results, including the energetics and spectral weight of Hubbard sidebands and QP renormalization [3,8,11,12]. Meanwhile, a recent *GW* + DMFT study (where *GW* refers to Hedin's *GW* approximation [13]) has suggested that bulk SrVO₃ is weakly correlated [14].

The importance of electron correlations in a system may be gauged in terms of the ratio *U*/*W*, where *W* is the bandwidth. This ratio is known to be significantly enhanced at the SrVO₃ surface [15,16] and in few-layer systems [17,18]. However, such systems have reduced coordination at the surface, which is often complicated by reconstruction and relaxation [16]. For example, an insulating phase has been observed in SrVO₃ thin films for thicknesses <~6 unit cells, which was attributed to dimensional crossover due to reduced coordination [17,19]. In bilayer SrVO₃, a DFT + DMFT study has established that a Mott insulator emerges due to crystal field (CF) effects [18]; similar CF-induced insulating phases are predicted in other vanadates [20–23]. Although QW structures are well known in semiconducting [24] and free electronlike [25] materials, their application to correlated 3d metals has only recently been realized in a select few transition metal oxides [26,27], including in few-layer SrVO₃ thin films [28]. However, the precise nature of these states, including their unusual subband renormalization [28,29], is not yet well understood, although this is essential to exploit their properties.

Here, we show that quantum confinement can be employed to precisely control strongly correlated electron behavior. We reveal the microscopic mechanism involved using a combination of DFT, DFT + DMFT, and tight-binding (TB) models applied to the prototypical correlated oxide SrVO₃, which we embed within layers of SrTiO₃ in a SL for direct comparison with previous experimental results [5]. Our results accurately reproduce the trends of the experimental data and reveal that the microscopic mechanism for the MIT in SrVO₃/SrTiO₃ SLs is due to quantum confinement. Our results also shed light

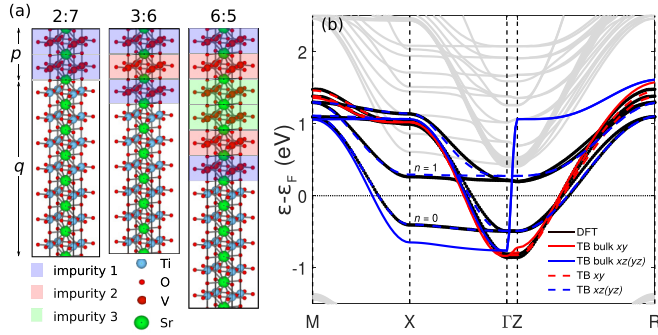

FIG. 1. (a) Schematic diagram of the superlattice (SL) structures, where p and q represent the number of SrVO_3 and SrTiO_3 layers, respectively. The SL unit cells used in the density functional theory (DFT) are indicated by the black boxes. The color-coded layers illustrate the impurities used in the dynamical mean-field theory (DMFT) calculation. (b) Quantized tight-binding (QT) bands for the 2:7 SL. The colored dashed lines indicate the intrinsic bulk bands from which the quantized bands are derived (see text). The discrete energies from the DFT calculation are shown for comparison (both V and Ti t_{2g} bands are given). The gray bands are non-V t_{2g} .

on previous observations of anomalous mass enhancement in SrVO_3 QWs [28,29], which can be naturally explained as consequences of quantization. These results present a means of controlling correlated electronic properties using quantum confinement as a control parameter. We demonstrate that the flexibility and range of control is much greater than that achievable through conventional means of adjusting the bandwidth, e.g., substitutional doping of single crystals. The possibility of controlling the bandwidth of a correlated material, and therefore the importance of electron correlations, opens up opportunities toward manipulating the electronic structure of this rich class of materials [30].

II. THEORETICAL METHODS

DFT calculations were performed using the all-electron full potential augmented plane-wave ELK package [31] within the local density approximation (LDA). Details about the DFT calculations are provided in Appendix B. The results are in excellent agreement with previous pseudopotential calculations [5]. The structures of the $(\text{SrVO}_3)_p/(\text{SrTiO}_3)_q$ SLs are shown in Fig. 1(a) for the three SLs investigated here, with $p:q = 2:7, 3:6$, and $6:5$. These were chosen for direct comparison with previous experimental results [5,32]. Experimental lattice parameters were used: the in-plane parameters were those of the $(\text{LaAlO}_3)_{0.3}(\text{Sr}_2\text{TaAlO}_6)_{0.7}$ (LSAT) substrate $a = b = 3.868 \text{ \AA}$, and out-of-plane parameters were $c_{2:7} = 4.00 \text{ \AA}$, $c_{3:6} = 3.97 \text{ \AA}$, and $c_{6:5} = 3.92 \text{ \AA}$. Additional calculations were performed using relaxed atomic positions and lattice parameters, leading to similar qualitative behavior. Even in the absence of the SL heterostructure, the different in- and out-of-plane lattice parameters weakly break the V t_{2g} degeneracy into $3d_{xy}$ and $xz(yz)$ orbitals.

To interpret our results, the LDA results for each SL were parameterized using a quantized Bohr-Sommerfeld TB (QT) model [25] (see Appendix C for further details). In this model, the *shape* of the TB bands was fixed to that of bulk SrVO_3 , and

the free parameters represent the band centers, bandwidths, and quantization parameters. In this way, CF splitting and band narrowing between xy and $xz(yz)$ orbitals can be fully captured. The results of fitting this model to the full ELK calculation is shown in Fig. 1(b) for the 2:7 SL, demonstrating the excellent agreement between the two. The quantized nature of the V $xz(yz)$ orbitals is clearly evident, leading to two subbands ($n = 0, 1$) originating from the two SrVO_3 layers. In Fig. 1(b), we also show the “intrinsic” TB bands, which correspond to bulklike bands before the quantization conditions are applied and represent the intrinsic three-dimensional (3D) electronic structure from which the QW states emerge.

For the DMFT calculation, we employed the TRIQS/CTHYB continuous-time quantum Monte Carlo (CTQMC) solver [33] in the TRIQS library [34], along with the previously used Hubbard-Kanamori interaction Hamiltonian $\beta = 40 \text{ eV}^{-1}$ ($\sim 290 \text{ K}$), $J = 0.75 \text{ eV}$, and fully localized limit double counting term [18,20,21]. The DMFT cycle requires multiple impurities depending on the SL structure, as illustrated schematically in Fig. 1(a). The systems investigated correspond to a single impurity for the 2:7 SL and bulk calculations, and two and three impurities for the 3:6 and 6:5 SLs, respectively. In each case, the impurities are considered independent of one another. Only the (projected) V t_{2g} states (using Wannier projectors [35]) were treated as correlated in the DMFT calculation.

As in recent studies [36], the results presented use the fully charge self-consistent DFT + DMFT technique as implemented in the TRIQS/DFTTools library [37]. We obtain similar results with the one-shot approach with the exception of the orbital charges (see Appendix D), which is consistent with other studies [20–22]. For each SL structure, U was varied in the range $5.5\text{--}6.25 \text{ eV}$, and U_{MIT} was located, corresponding to the U at which the SL becomes insulating. In Fig. 2(a), we show the orbitally averaged QP residue $\bar{Z} = (\sum_i Z_i)/N$ for each SL, showing how U_{MIT} increases by $\sim 0.2 \text{ eV}$ for each SL. Here, Z_i was determined from the i th orbital self-energy on the Matsubara frequency axis.

III. RESULTS

We begin by ensuring that our DFT + DMFT calculations accurately describe the experimental system. In Figs. 2(b)–2(d), we compare quantities extracted from x-ray absorption spectroscopy (XAS) and resonant inelastic x-ray scattering (RIXS) experiments [5] with the corresponding theoretical quantities from our DFT + DMFT calculations for $U = 5.7 \text{ eV}$, chosen to reproduce the phenomenological behavior of the experiments. As demonstrated by Figs. 2(b)–2(d), our DFT + DMFT calculations not only capture the qualitative behavior, but also yield excellent quantitative agreement with the experiment trends. Our chosen U value is in good agreement with previous constrained random phase approximation calculations of relaxed freestanding layers of SrVO_3 [18]. Additional calculations using the GW method demonstrate the insulating state evolves due to strong electron correlation and not due to the effects of nonlocal exchange (see Appendix D). We note that, although the 2:7 SL is macroscopically insulating, it has a small QP spectral weight in the spectroscopic experiments due to properties of the sample.

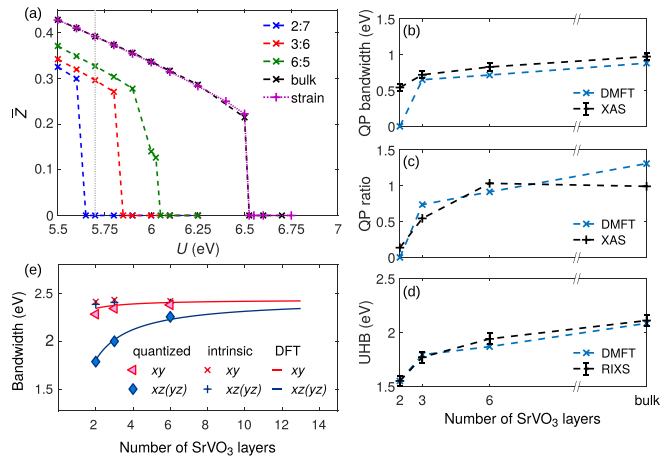

FIG. 2. (a) The orbitally averaged quasiparticle (QP) residue \bar{Z} for each of the $p:q$ superlattices (SLs). Also shown are the results of bulk and 1% strained calculations (see text). The gray dotted line indicates the value of $U = 5.7$ eV used for subsequent calculations. (b)–(d) Comparison with experimental quantities from x-ray absorption spectroscopy (XAS) and resonant inelastic x-ray scattering (RIXS) data (see Appendix A) [5]: (b) QP bandwidth; (c) spectral weight within QP states compared with upper Hubbard band (UHB) states; (d) energy of UHB [the dynamical mean-field theory (DMFT) results have been rigidly shifted to match at the 2:7 SL]. (e) The bandwidths of the SLs from the density functional theory (DFT) calculation and quantized tight-binding (QTB) model. Also shown are the intrinsic (bulk) bandwidths of the QTB model.

Insight into the microscopic mechanism for the MIT can be obtained by analyzing the QTB model for each SL. In Fig. 2(e), the bandwidths of the SLs from the DFT calculations are shown alongside those from the QTB model. While the in-plane xy orbitals experience a slight narrowing for thinner SrVO_3 SLs, the overall band narrowing of the (quantized) out-of-plane $xz(yz)$ orbitals is substantial, leading to a bandwidth reduction of $\sim 70\%$ for the 2:7 SL [5]. As expected from the quality of the fits in Fig. 1(b), good agreement is observed between the QTB and DFT results. However, this behavior is not captured at all by the intrinsic bandwidths, which correspond to the effective 3D bands of the QTB model before quantization. These results demonstrate that the band narrowing in Fig. 2(e) is due to quantization of the $xz(yz)$ orbitals, which has a more pronounced impact for thinner SrVO_3 layers. The band narrowing of the thinner SLs leads to a greater U/W ratio, which results in stabilization of the insulating phase, as illustrated by the DFT + DMFT calculations shown in Fig. 2(a).

A previous DMFT study has attributed CF effects as being the principle factor driving the MIT in bilayer SrVO_3 on SrTiO_3 [18], and it is pertinent to ask what role, if any, the CF plays in our system. In Ref. [18], strain induced by the SrTiO_3 substrate led to a lowering of the xy orbitals by 180 meV due to the CF. In contrast, we find a CF splitting of ≤ 51 meV in favor of the V $xz(yz)$ bands in our SLs, in part owing to the lower strain imparted by the LSAT substrate. To reproduce the effects of this CF, we have calculated strained SrVO_3 with a volume-conserving strain of 1%, which leads to similar CF splitting of 53 meV (see Appendix D for more details).

This 3D system, which reproduces the CF levels of our SLs but without the quantization effects, is shown in Fig. 2(a) and shows very similar behavior to the bulk cubic system. Therefore, we confidently rule out CF effects as a dominant factor in our SLs.

Finally, we discuss the correlated behavior of the quantized electron states, taking the 6:5 SL as an example. Figures 3(a)–3(c) show the orbital- and layer-resolved occupation number n_e , QP residue Z , and spectral weight at the Fermi level $A(\omega = 0)$ as a function of U , illustrating the transition to the insulating phase at $U = 6.05$ eV for this SL. As presented in Fig. 3(a), each layer (impurity) exhibits a sizable orbital polarization in favor of the xy orbitals, which is exaggerated both at the outer (interface) layer and in the insulating phase. This behavior is consistent across all SLs and originates from a small polarization in the DFT calculations due to the local CF, which is subsequently amplified in the DMFT cycle (see Appendix D). The outer layer (impurity 1) is significantly “more correlated,” experiencing a smaller QP residue Z than the other layers [Fig. 3(b)], corresponding to a greater renormalization factor $1/Z$. Near the MIT, this leads to a collapse in the spectral weight at $\omega = 0$ of the interface layer [Fig. 3(c)]. In this sense, the more correlated interface layer simultaneously triggers the MIT in the remaining layers, in much the same way as suggested for SrVO_3 bilayers in Ref. [18].

The DMFT spectral functions $A(\omega)$ and $A(\mathbf{k}, \omega)$ are shown in Figs. 3(d)–3(f) and Figs. 3(h)–3(j) for $U = 5.7$, 6.025, and 6.05 eV, respectively, and were calculated using the maximum entropy method within TRIQS [38]. The renormalization of the V bands increases from a factor of $1/\bar{Z} \approx 3.5$ at $U = 5.7$ eV to ≈ 8 just below the MIT ($U_{\text{MIT}} = 6.05$ eV) before the QP spectral weight vanishes in the insulating phase [Fig. 3(f)]. The renormalization of the V bands is accompanied by a lowering in their energy with respect to O and Ti bands, leading to pronounced energy separation of O/Ti bands and metallic V t_{2g} QPs. Nevertheless, the quantized subband structure remains clear in the metallic solutions, leading to genuinely strongly correlated QWs. At $U = 5.7$ eV, the lowest three yz subbands are occupied at X and Γ , like the DFT; however, by $U = 6.025$ eV, only the lowest subband is occupied, indicating the quantized system undergoes a correlation-induced Lifshitz transition before the MIT. Although the correlated orbitals remain relatively sharp throughout near $\omega = 0$, implying long-lived QPs with a well-defined Fermi surface, the lifetime rapidly broadens away from ε_F , in line with a strongly correlated Fermi liquid (see inset to Fig. 4). We also note that the incoherent upper Hubbard band (UHB), visible >1 eV in [Fig. 3(j)], exhibits rather strong momentum dependence, visible in previous bulk DMFT calculations [11,39]. Unexpectedly, certain (uncorrelated) Ti states also show pronounced broadening, e.g., the $n = 1$ Ti yz orbital indicated in Fig. 3(h), which is almost completely smeared out at $U = 6.025$ eV [Fig. 3(i)]. This arises due to the spatial penetration of the Ti wave functions at the interface into the correlated SrVO_3 layers, leading to broadening of those subbands that have significant weight at the interface (see Appendix B). This surprising sensitivity of the Ti states may help to explain recent RIXS results of the $\text{SrVO}_3/\text{SrTiO}_3$ SLs, where a sudden change in the delocalized

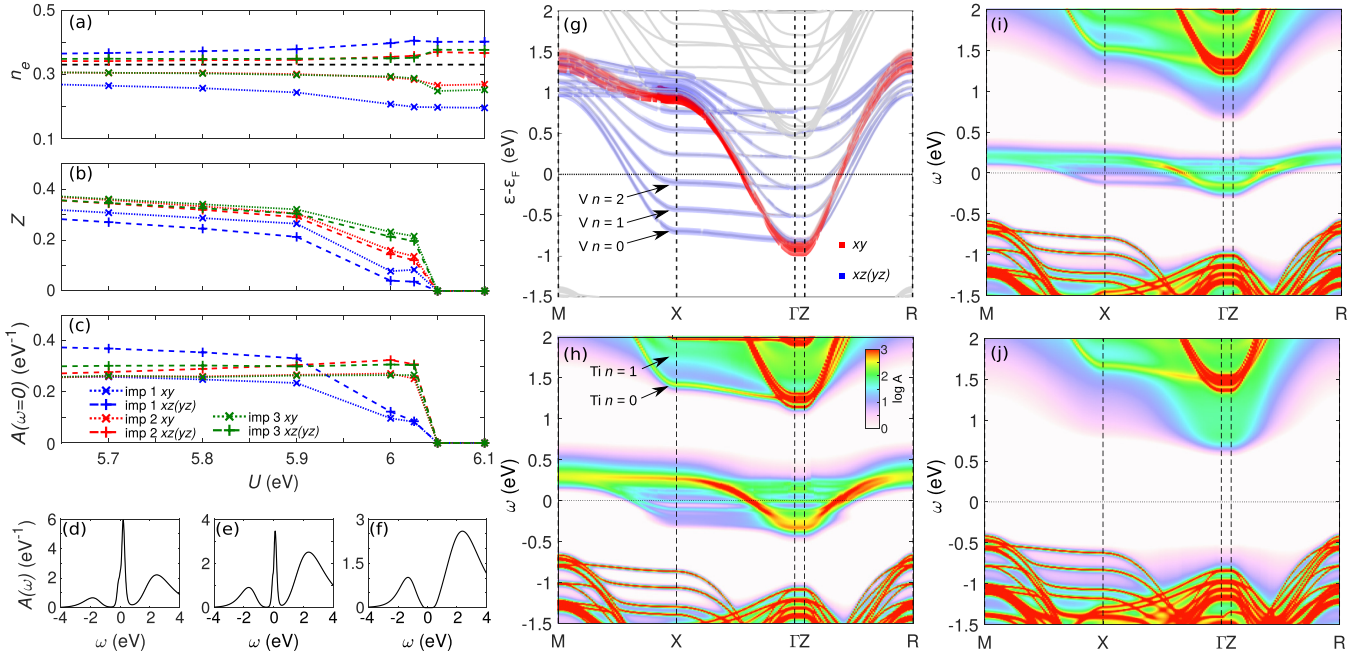

FIG. 3. Correlated quantum well (QW) electronic structure. (d)–(f) The momentum-integrated $V t_{2g}$ spectral function $A(\omega)$ for $U = 5.7, 6.025$, and 6.05 eV, respectively. (g) DFT band structure of the 6:5 SL, with $V t_{2g}$ band characters shown. (h) DFT + DMFT momentum-resolved spectral function $A(\mathbf{k}, \omega)$ of the 6:5 SL for $U = 5.7$ eV, showing directly the renormalization of the correlated bands. (i) and (j) DFT + DMFT spectral function close to the MIT for $U = 6.025$ and 6.05 eV, respectively.

Ti $3d$ carrier density was observed coincident with the MIT of the SrVO_3 layers [40].

We finish by discussing some important implications of our results. Anomalous mass enhancement has been reported in SrVO_3 QWs, whereby shallower occupied subbands were found to have a larger mass enhancement ($m^* = m/Z_v$) than subbands at deeper energies [28]. Subsequent theoretical [41] and experimental [29] studies argued the anomalous enhancement was a consequence of a combination of electron

correlation effects and the reduced dimensionality of the surface. To address this, we compare the total mass enhancement of a particular quantized subband $1/Z_v$ with that due solely to electron correlation $1/Z_v^c$, both of which are obtained through analysis of the Fermi velocities (see Appendix D for more details). The trend in the total mass enhancement factor $1/Z_v$, which includes both correlation effects and band effects due to quantization, qualitatively reproduces the experimental data [28] rather well, but this behavior is only very weakly present in $1/Z_v^c$. Therefore, in our SLs, the origin of the mass enhancement is firmly due to k_z sampling introduced by quantization, as has been observed in other systems [27]. While reduced coordination at the surface [16,41], surface reconstruction [42], or specific k_z sampling due to an asymmetric phase shift at the vacuum [27,43] may play additional roles in specific surface-terminated systems, our results reveal quantization as the primary source of anomalous mass enhancement in embedded (or capped) few-layer SrVO_3 .

IV. CONCLUSIONS

In summary, our results establish quantum confinement engineering as a sensitive method to tune the correlated electron behavior of $3d$ electron systems. We demonstrate our approach using SLs of few-layer SrVO_3 embedded in SrTiO_3 : this system exhibits an MIT due to a reduction in bandwidth by varying the number of SrVO_3 layers. The microscopic mechanism we reveal is a direct consequence of quantum confinement and is distinct from previous studies invoking CF effects [18] or dimensionality [17], demonstrating the

FIG. 4. The total mass enhancement factor of each subband $1/Z_v$ of the 6:5 SL at $U = 5.7$ eV shown alongside the correlation-only mass enhancement factor $1/Z_v^c$, evaluated along X - M . All lines are guides to the eye.

excellent versatility of the MIT in SrVO_3 with respect to different control parameters. Like Ref. [18], we find that the outer layers at the interface of the QW are more strongly correlated and trigger the transition in the rest of the layer. Our interpretation can also naturally explain the anomalous mass enhancement previously reported in angle-resolved photoemission spectroscopy measurements [28,29]. Together, these results demonstrate the potency of employing quantum confinement as a tuning parameter for correlated electron behavior in engineered SLs. This approach also has the significant benefits that surface effects are avoided and that large (bulklike) volumes of the system may respond to external stimuli. Aside from the expected improved performance of such a SrVO_3 device as a Mott transistor [18], quantized SLs made of other correlated materials are likely to show improved properties, e.g., superconducting devices in cuprate SLs [44], conductivity in nickelate SLs [45], or spintronic devices [46].

Data are available at the University of Bristol data repository, data.bris, at [47].

APPENDIX A: COMPARISON WITH EXPERIMENTAL QUANTITIES

Figure 5 illustrates the main experimental spectroscopic results on the SLs [5,32], in which transport measurements established that the 2:7 and 3:6 SLs were insulating, whereas the 13:4 SL was metallic. The 6:5 SL was found to be metallic at room temperature, with an MIT at low temperature. The experimental results (performed at room temperature) show the evolution in correlated electron behavior extracted from XAS and RIXS.

For completeness, we briefly outline the experimental properties and how they were extracted here. The metallicity [Fig. 5(a)] was extracted from both XAS and RIXS as the leading edge of the O K edge XAS and from the intensity of the quasi-elastic peak in V L edge RIXS. The QP bandwidth [Fig. 5(b)] was extracted from the SrVO_3 layer contribution to the O K edge XAS as the full width at half-maximum of the QP peak. The QP spectral weight [Fig. 5(c)] was also extracted from the SrVO_3 layer contribution to the O K edge XAS as the ratio of the area under the QP peak to the total area under unoccupied V $3d$ states (i.e., the sum of QP, UHB, and e_g spectral weights). Occupied states are not accessible in O K edge XAS. Finally, the UHB energy [Fig. 5(d)] is accessible to both XAS and RIXS. From O K edge XAS, the UHB peak

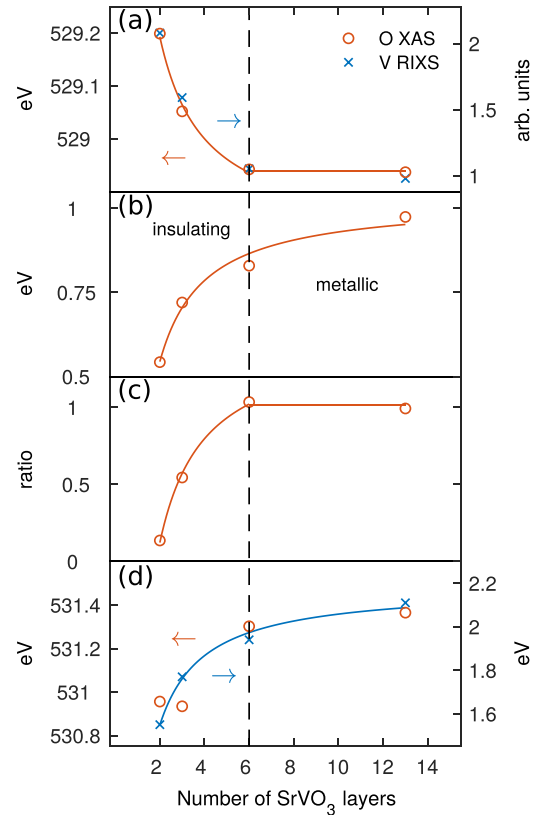

FIG. 5. Evolution of correlated electron behavior from experimental x-ray absorption spectroscopy (XAS) and resonant inelastic x-ray scattering (RIXS) measurements of $\text{SrVO}_3/\text{SrTiO}_3$ superlattices (SLs), reproduced from Ref. [5]. From top to bottom, evolution in (a) metallicity of SLs, (b) quasiparticle (QP) bandwidth, (c) QP spectral weight, and (d) the energy of the upper Hubbard band (UHB) are shown.

is directly observed, and its center is shown here. From V L edge RIXS, the UHB energy is available from transitions from occupied QP states to the unoccupied UHB. Both show equivalent evolution with SL structure.

Figure 6 shows a schematic illustration comparing the extracted experimental quantities with their DFT + DMFT definitions. The QP bandwidth has been extracted from the DMFT spectral function by obtaining the width defined by the minima around the central QP peak. The QP ratio was determined by taking the ratio of the the QP weight (labeled Q in Fig. 6) and the UHB weight (labeled U). Finally, the energy of the UHB was obtained by locating the peak in the DMFT spectral function, referenced to $\omega = 0$. In the experimental RIXS process, the UHB peak energy represents the peak in the joint QP and UHB density of states and therefore is referenced to an energy $\omega < 0$. To compare the theoretical and experimental UHB energies, we therefore shift all theoretical UHBs so that the 2:7 SLs match (the shift is -0.584 eV).

APPENDIX B: DFT CALCULATIONS

DFT calculations were performed using the ELK full potential linearized augmented plane-wave (FP-LAPW) code within the LDA [31]. The results are in excellent agree-

FIG. 6. A schematic illustration showing how the variables in the theory-experimental comparison were determined.

ment with previous pseudopotential calculations within the generalized gradient approximation (GGA) of the same SLs [5]. Previous photoemission spectroscopy work [17] shows how the dimensionality of SrVO₃ influences the MIT. In their results, 10 SrVO₃ layers closely resemble bulk behavior. From this, we approximate the 13:4 SL in Ref. [5] with bulk DFT + DMFT calculations.

Self-consistency was achieved on a $12 \times 12 \times 4$ k -mesh in the full Brillouin zone (BZ) for relatively low computational cost with sufficient sampling, corresponding to 84 k -points in the irreducible ($\frac{1}{16}$) BZ. To stabilize the DFT self-consistent cycles, small values of mixing of the new potentials was used, at the cost of computational time. For bulk SrVO₃, a k -mesh of $12 \times 12 \times 12$ was used (84 k -points in the $\frac{1}{48}$ irreducible BZ).

The partial densities of states (PDOS) of t_{2g} orbitals are shown in Fig. 7 for the bulk and 2:7, 3:6, and 6:5 SLs. Sharp peaks in the PDOS reflect the quantized electronic structure along c . For the inner layers of the thicker SLs, the PDOS more closely resembles that of bulk SrVO₃, e.g., impurity 3 of the 6:5 SL. Near the interface, the $xz(yz)$ PDOS extends to higher energies as a result of mixing of these states with Ti states in the SrTiO₃ layer.

The characters of the subbands are shown in Fig. 8 for each of the different V and Ti sites, using the 6:5 SL as an example. As expected, the V bands dominate the character at the Fermi level, with weak contribution from interfacial Ti ions. The spatial distribution of the subband wave functions of the SrVO₃ QWs can be seen directly in the characters. The V $n = 0$ subband, with greatest amplitude in the center of the well, has strong character in the central V ion and weak character at the interface. Correspondingly, the V $n = 2$ subband has the strongest character at the interface and is almost absent in the second layer close to where a node is expected in the QW wave function. At higher energies, the quantized V e_g subbands appear > 1 eV.

The Ti band characters shed light on the broadening of the Ti bands in the DFT + DMFT calculations shown in Fig. 3. As above, the central Ti ion contributes strongly to the Ti $n = 0$ and 2 subbands. On the other hand, the interfacial Ti ion contributes significantly to the Ti $n = 1, 2$, and 3 subbands, with the largest contribution to the Ti $n = 2$ subband. The interfacial Ti ion mixes most strongly with the V orbitals, which are the correlated orbitals in the subsequent DMFT cycle. This demonstrates how the spatial penetration of the Ti $n = 1$ and 2 subbands into the correlated SrVO₃ layers leads to substantial broadening of these subbands in the subsequent DMFT cycle. In contrast, the Ti $n = 0$ subband is spatially deep within the SrTiO₃ layer and does not feel the effects of the correlated SrVO₃ orbitals very strongly, remaining reasonably sharp even in the insulating phase [Fig. 3(j)].

APPENDIX C: QTB MODEL

1. Bulk TB bands

The TB model was constructed up to 12th nearest neighbors, consisting of 24 hopping terms t_i up to $[l, m, n] = [2, 2, 2]$. For the xy band, the TB dispersion ε_{xy} is given by

$$\varepsilon_{xy} = E_{xy}^0 + \sum_{lmn} t_{xy}^{lmn} \cos(lk_x + mk_y + nk_z), \quad (C1)$$

where the band energy E_{xy}^0 corresponds to the CF energy. Since the purpose of our model is to accurately describe the bulk 3D DFT band structure, we do not attempt to analyze individual parameters, as has been done before [15]. Although terms corresponding to the fifth nearest neighbor and higher had a magnitude of < 10 meV, these terms were found to be necessary to adequately describe the FP-LAPW band structure. After fitting this model to the bulk LDA band structure in the full cubic BZ, we find the root-mean-square difference is < 11 meV, with a maximum difference of 70 meV.

2. Quantum confinement

To account for the effects of quantum confinement of the V 3d electrons in the SrVO₃ layers, we apply the Bohr-Sommerfeld phase accumulation model [25]:

$$2k_z^n(E)L + \delta(E) = 2\pi n, \quad (C2)$$

where $n = 0, 1, 2, \dots$ is the quantum number, $2k_z^n(E)L$ is the total phase accumulated in traveling through the SrVO₃ layer and back, $k_z^n(E)$ is the quantized out-of-plane wave vector, $L = mc$ is the SrVO₃ layer thickness (m and c are the number of SrVO₃ layers and c -axis lattice parameter of the SrVO₃ layers, respectively), and $\delta(E)$ is the total phase acquired due to reflection at both SrVO₃/SrTiO₃ interfaces. For asymmetric QWs, e.g., thin overlayers with a vacuum interface, $\delta = \phi_1 + \phi_2$ is composed of different individual phase shifts at each reflection; in our case of symmetric barriers, $\delta = 2\phi$, where ϕ is the phase at a single SrVO₃/SrTiO₃ interface. In general, $\delta = \delta(E)$ is explicitly dependent on the energy of the confined state. However, to simplify the fitting and avoid unnecessary degrees of freedom, we instead implicitly include the energy dependence through different phases for each quantum number $\delta = \delta_n$. With this, the quantization condition

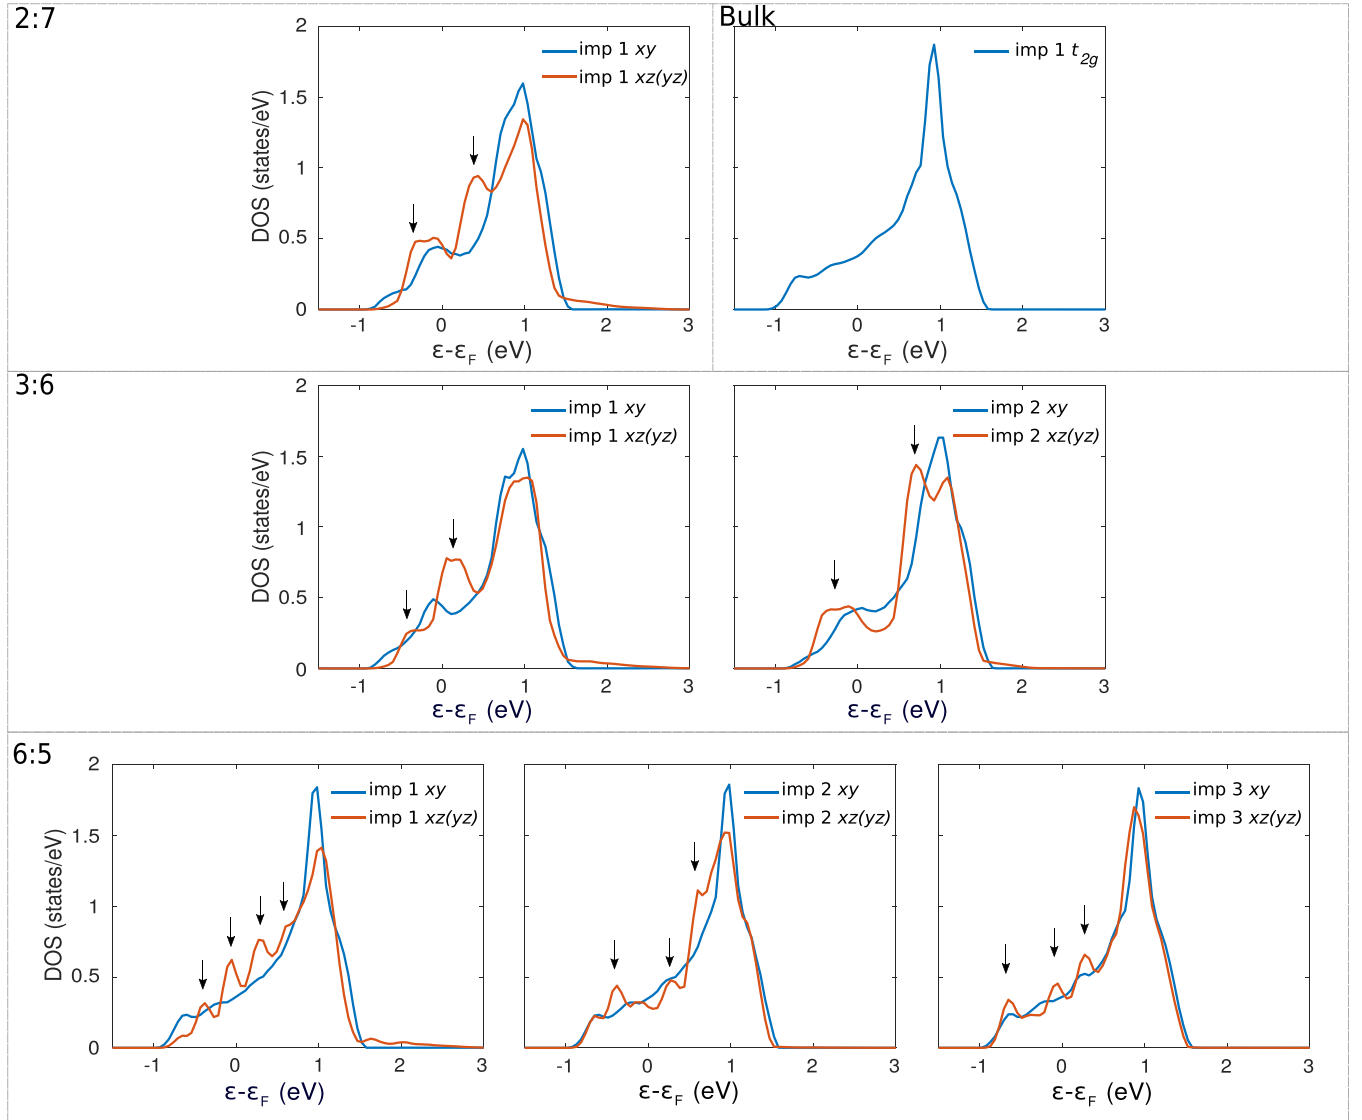

FIG. 7. The density functional theory (DFT) $V t_{2g}$ partial density of states (PDOS) of the bulk SrVO_3 , 2:7, 3:6, and 6:5 SLs. The dashed borders outline which plots belong to the corresponding structure. Each panel shows the PDOS of the inequivalent V atoms in each structure, labeled by their impurity number in the dynamical mean-field theory (DMFT) cycles (imp 1 refers to the interface). The arrows indicate the contributions of quantized states to each inequivalent V atom. The greatest contribution is from the relatively flat bands along Γ -X.

reduces to

$$k_z^n = \frac{2\pi n - \delta_n}{2mc}, \quad (\text{C3})$$

from which the quantized TB dispersion $E_n(k_x, k_y, k_z^n)$ may be evaluated.

3. Full quantization parameters

For each SL, four parameters were fitted to describe the intrinsic band structure, and n parameters described the confined bands. The quantized TB dispersion was fitted to the FP-LAPW ELK band structure of the SLs. The four intrinsic parameters consist of band centers $[E_i^0$ in Eq. (C1)] and band widths for the xy and $xz(yz)$ bands. The band width parameter W_i is a multiplicative factor to the hopping terms t_i (the hopping terms themselves were fixed to the cubic bulk parameters

determined above, effectively fixing the shape of the band). In addition to the intrinsic parameters, the phase shifts for each confined state δ_n were also fitted. The fitted phases are shown in Fig. 9 against the mean energy of each state and closely follow the same roughly linear relationship with energy for all SLs.

The results of fitting the FP-LAPW bands to the quantized TB model are shown in Table I, separated into contributions from the underlying bulk intrinsic bands and after quantizing these bands. An example of the fitted band structure is shown in Fig. 1 for the 2:7 SL. Since its wave function is perpendicular to the quantization axis, the xy bandwidth is hardly affected by confinement, but the $xz(yz)$ bands are significantly narrowed compared with their intrinsic (bulklike) counterparts. The confinement leads to the preferential filling of the quantized $xz(yz)$ out-of-plane bands as their k_z dispersion is

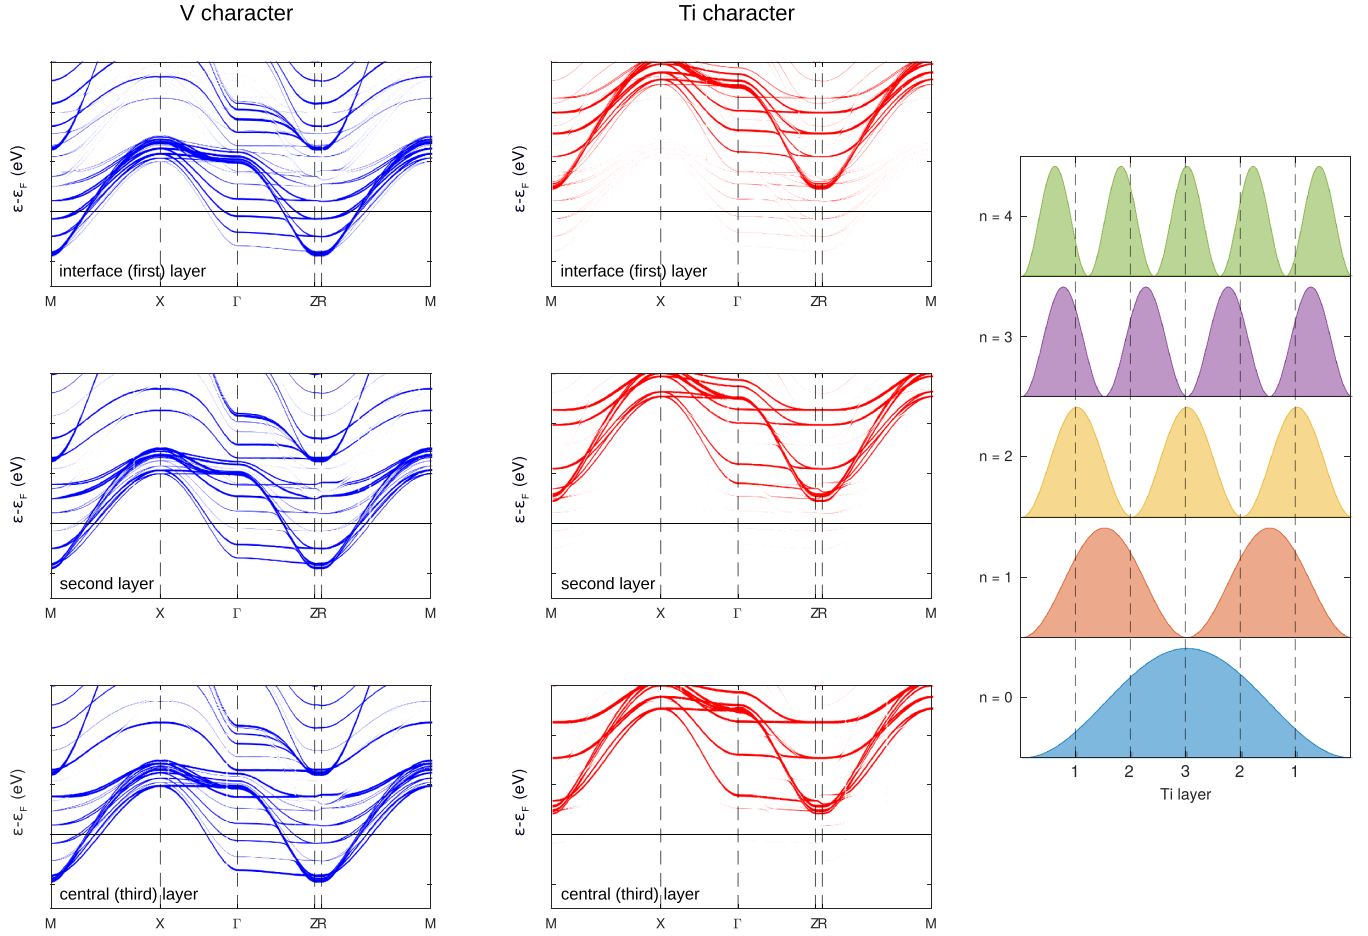

FIG. 8. The density functional theory (DFT) V and Ti t_{2g} band characters of the 6:5 superlattice (SL). The thickness of the lines indicates the total character of each V (left) and Ti (right) site. The top row shows the band characters at the interface, while the bottom row shows the character in the center of each layer. On the right, a schematic illustration of the real-space probability distribution of the quantized subbands in the out-of-plane direction of the SrTiO₃ layers is shown. The edge of the box does not coincide with the interface Ti ion or its neighboring SrO layer due to the finite phase accumulated at the interface.

suppressed and they become 1D-like, which also pulls the Fermi level down slightly.

We note that confinement alone is capable of reproducing the SL band structure to a large extent, correctly describing the narrowing of the quantized bandwidth and its variation with SrVO₃ layer thickness. This has been checked by restricting the intrinsic bands in the fit to the bulk bands (i.e., setting E_i^0

and W_i to the bulk ones). This provides additional support that the band narrowing that eventually drives the MIT is primarily due to quantization effects rather than CF effects.

APPENDIX D: DMFT CALCULATIONS

The output from the ELK DFT calculation was imported to the TRIQS library [34] via an in-house interface with the DMFTPROJ [37] application. As in the literature [18,20,21],

FIG. 9. The phase shift at the SrVO₃/SrTiO₃ interface for each quantized state in the superlattices (SLs; note $\phi_n = \delta_n/2$ is shown), shown against the mean band energy.

TABLE I. Results of fitting the FP-LAPW ELK bands to a QTB model. The CF splitting is the energy difference $E_{yz}^0 - E_{xy}^0$. The bandwidth (relative to bulk SrVO₃) W_i of the xy and yz bands is shown for both intrinsic bands (before quantization) and for the quantized bands, alongside their anisotropy (W_{yz}/W_{xy}).

SL	CF splitting (meV)	Intrinsic			Quantized bands		
		W_{xy}	W_{yz}	Anis.	W_{xy}	W_{yz}	Anis.
6:5	33	0.966	0.959	0.993	0.950	0.900	0.948
3:6	40	0.971	0.960	0.989	0.935	0.798	0.853
2:7	51	0.963	0.952	0.988	0.911	0.713	0.782

only the V t_{2g} bands were projected (using Wannier projectors) [35] to construct the LDA Hamiltonian in Wannier space. These projectors were constructed in the following correlated energy windows: 2:7 SL, $[-1.36, 2.0]$ eV; 3:6 SL, $[-1.29, 2.0]$ eV; 6:5 SL, $[-1.29, 2.0]$ eV; and bulk, $[-1.50, 1.90]$ eV. These windows were constructed such that all of the V t_{2g} bands are included, and the valence charge above the lower bound, corresponding to the charge in the V t_{2g} orbitals, is equal to 1 per V impurity. Each DMFT cycle calculation used 84×10^6 Monte Carlo sweeps.

To avoid potential complications from the ill-posed problem of analytic continuation, many quantities were determined from the Green's function and self-energy on the imaginary time (τ) or Matsubara frequency axis. The charge of each orbital (n_e) was determined by

$$n_e = \frac{1}{\beta} \sum_n G(i\omega_n) e^{i\omega_n 0^+}, \quad (D1)$$

within the TRIQS library. As there is negligible interorbital-orbital overlap on the impurity, the n_e orbital charge matrix is diagonal. The spectral function at the Fermi level is determined directly from the imaginary time Green's function by [18]

$$A(\omega = 0) = \frac{\beta G(\tau = \frac{1}{2}\beta)}{\pi}, \quad (D2)$$

where β is the inverse temperature. The $A(\omega = 0)$ here is an averaged quantity over a frequency window $\sim \beta^{-1}$. The value of QP residue Z was determined by

$$Z = \left\{ 1 - \frac{\partial \text{Im} [\Sigma(i\omega_n)]}{\partial i\omega_n} \bigg|_{i\omega_n \rightarrow 0^+} \right\}^{-1}, \quad (D3)$$

where the Z is evaluated from the differential of the imaginary part of the Matsubara self-energy at $i\omega_n \rightarrow 0^+$. For U values far from the Fermi liquid regime (namely, for the 6:5 Z values close to the MIT), the Z values were approximated by using the differential of the interpolated self-energies at $i\omega_n = 0$. There are two ways to realize the insulating solution: first, by a divergence in $\text{Im}[\Sigma(i\omega_n)]$, which comes naturally with $Z = 0$. Second, the combination of the $\text{Re}[\Sigma(i\omega_n)]$ and the chemical potential might move the pole position outside of the noninteracting bandwidth, meaning that no QP peak is possible in the Green's function. In the latter case, we have $A(\omega = 0)$ vanishing with nondiverging $\text{Im}[\Sigma(i\omega_n)]$. In that case that we also see here, we set Z to zero manually. From this, the MIT U value (U_{MIT}) is defined as the lowest U value in which $A(\omega = 0) = 0$.

The spectral functions $A(\omega)$ for each impurity were calculated from $G(\tau)$ using the LINEFITANALYZER technique of the maximum entropy analytic continuation method implemented within the MAXENT application of TRIQS [38]. The k -resolved spectral functions $A(\mathbf{k}, \omega)$ were calculated from the analytically continued self-energy.

The effective and correlation subband mass enhancement factors $1/Z_v$ and $1/Z_v^c$ were calculated from the ratios of the Fermi velocities using

$$Z_v^c = \frac{v_F^c}{v_F^{\text{QTB}}}, \quad (D4)$$

and

$$Z_v = \frac{v_F^c}{v_F^i}. \quad (D5)$$

Here, the Fermi velocities were determined from the gradient of the linearly expanded band dispersions along M - X around k_F of the DFT + DMFT subbands (v_F^c), the quantized bands from QTB (v_F^{QTB}), and the intrinsic (bulklike) TB bands (v_F^i). The intrinsic bands were used, as they incorporate the effect of renormalization due to strain. Therefore, Z_v^c and Z_v describe the effect of renormalization from correlations and the combination of correlations and confinement (band) effects, respectively.

The DFT + DMFT subband energy centers $E_{v,\mathbf{k}}$ were calculated by using

$$E_{v,\mathbf{k}} = \epsilon_{v,\mathbf{k}} - \mu + \text{Re}[\Sigma_v(\mathbf{k}, \omega = E_{v,\mathbf{k}})], \quad (D6)$$

where $\epsilon_{v,\mathbf{k}}$ is the DFT energy, μ is the chemical potential, and $\text{Re}[\Sigma_v(\mathbf{k}, \omega)]$ is the real part of the diagonal upfolded self-energy elements on the real frequency axis. The QP lifetime in the inset of Fig. 4 was determined from the inverse imaginary part of the analytically continued upfolded self-energy. Finally, the subband energies at the Γ high-symmetry point in Fig. 4 were determined from Eq. (D6).

1. One-shot and fully charge self-consistent DFT + DMFT results

The main text presents fully charge self-consistent (FCSC) DFT + DMFT calculations. Here, we present the results of one-shot (OS) DFT + DMFT for comparison. Overall, charge self-consistency slightly adjusts some details of the results, but the main conclusions of our paper are already present in OS calculations.

Figure 10 shows the U -dependent MIT for each SL and different DFT + DMFT methods. The behavior of the OS and FCSC calculations is very similar, exhibiting a U_{MIT} with comparable characteristics, e.g., $A(\omega = 0)$ and Z . Some differences are observed in the orbital polarization between the two methods, whereby the polarization is somewhat suppressed in the FCSC calculation compared with OS. This behavior, most notable for the 2:7 SL, is consistent with other studies [20–22] and is caused by the charge redistribution with the rest of the system at the DFT stage. This trend from 2:7 to bulk is also seen in Fig. 11 for the orbitally averaged values of Z , where there are some differences in \bar{Z} for the 2:7 SL between OS and FCSC, but the bulk values are very similar.

An important note to make about Fig. 10 is that Z at the interface (imp 1) for the $xz(yz)$ orbitals tends to zero first for each SL. This suggests that the weight from the $xz(yz)$ QP peak depletes first. Therefore, when the interface $xz(yz)$ QP state has been fully depleted, this causes the SL to transition into the insulating state. From this, the interface between the oxides has a strong influence on the MIT. The $A(\omega = 0)$ for imp 1 of the 6:5 also tends to zero which strengthens the argument for at least that SL.

Figure 12 shows the $A(\omega)$ of each correlated impurity orbital in each SL at $U = 5.7$ eV (the value used in the theoretical-experimental comparisons). It is evident that the 2:7 is insulating and the 3:6 and 6:5 are metallic from the

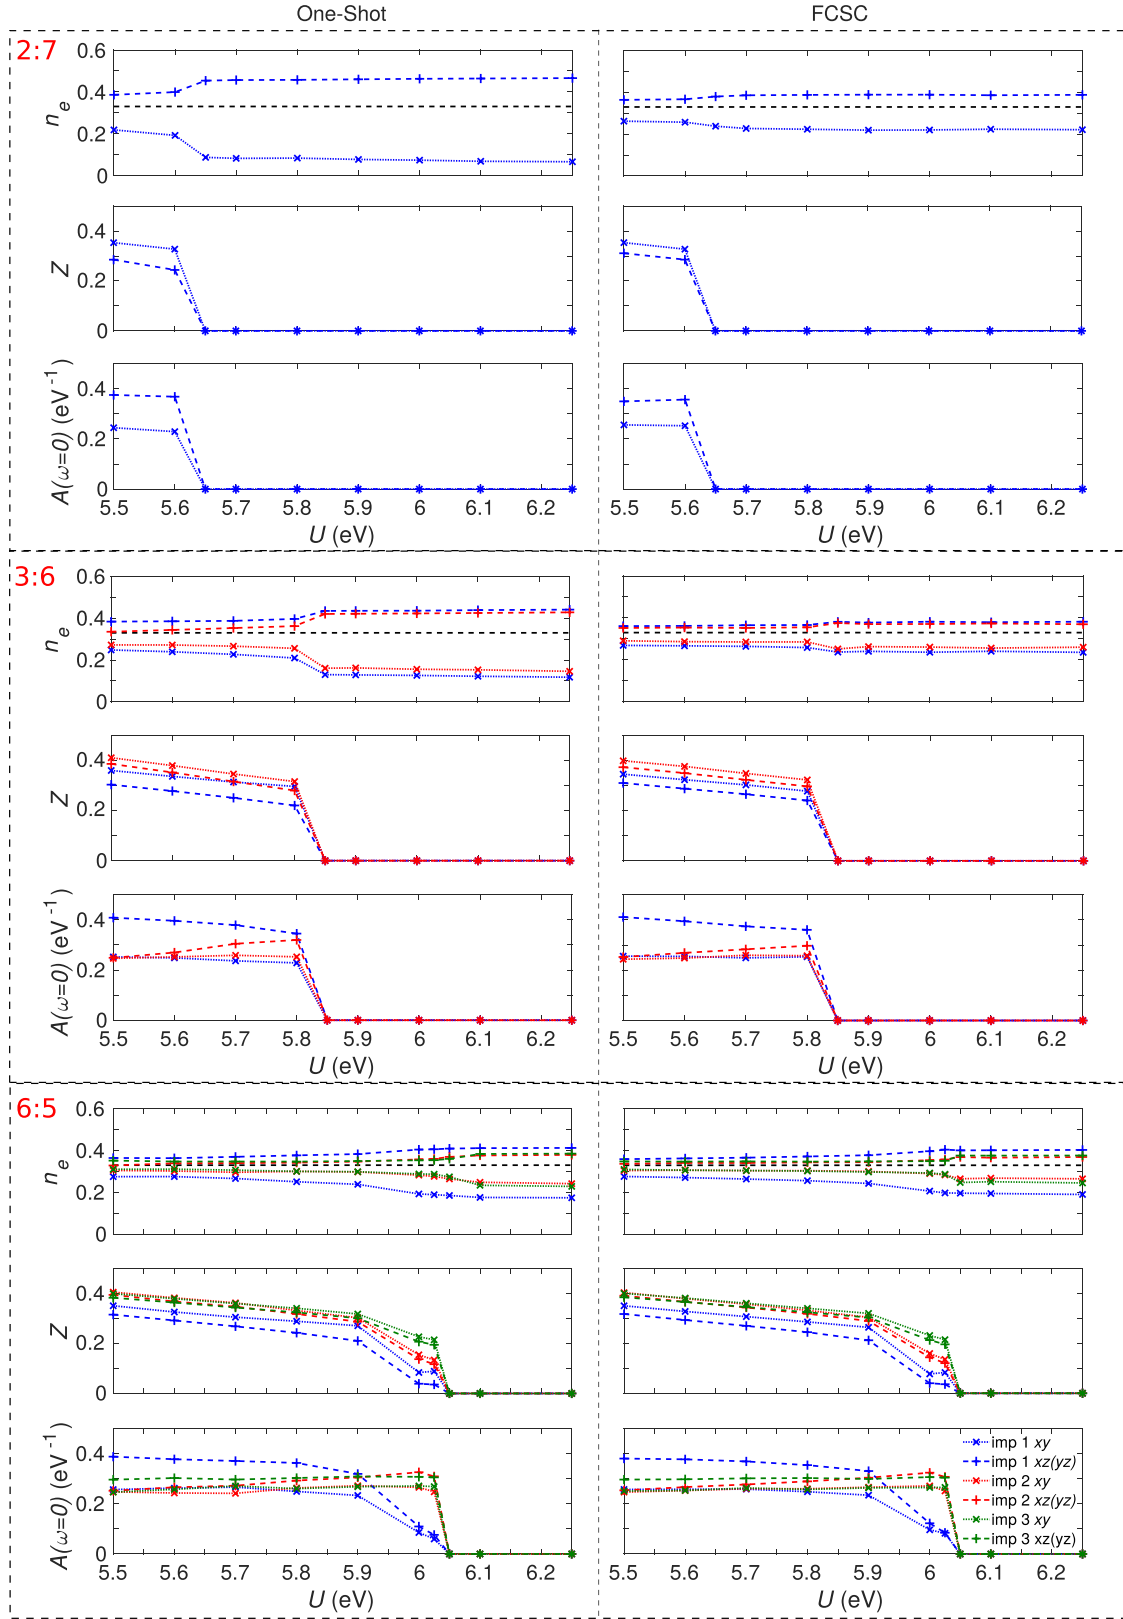

FIG. 10. The effect of U on the orbital charge n_e (top), quasiparticle (QP) residue Z (middle), and the spectral function around the Fermi level (bottom) for each superlattice (SL) one-shot (OS) and fully charge self-consistent (FCSC) density functional theory (DFT) + dynamical mean-field theory (DMFT) calculation. These quantities were extracted from the corresponding Green's functions and self-energies on either the imaginary time or Matsubara frequency axis. The dashed line represents the bulk degenerate orbital charge.

FIG. 11. The comparison of the orbially averaged quasiparticle (QP) residue \bar{Z} between the one-shot (OS) and fully charge self-consistent (FCSC) density functional theory (DFT) + dynamical mean-field theory (DMFT) methods. The plot lines are guides to the eye.

absence or presence of the QP peak at the Fermi level. There are sharp features in the QP peaks around the Fermi level for the 3:6 and 6:5 SLs. These features are often attributed to spurious noise from the analytic continuation procedure; however, it may not be the case here due to the quantized bands being present around the Fermi level. The peak position of the Hubbard bands (notably the UHB) are closer in energy to the Fermi level for the interface layer (impurity 1) than the other layers for the 3:6 and 6:5. This is another indication that the interface layer is more correlated than the other layers.

The trends across the SLs give further insight into the physical phenomena. The splitting of the orbital degeneracy strongly affects the polarization of the orbital charge, which is shown by the averaged Wannier orbital charge in Fig. 13. The reduction of the number of layers significantly increases

FIG. 13. The averaged orbital charge over all layers from the density functional theory (DFT) and DFT + dynamical mean-field theory (DMFT) Wannier V_{xy} and $xz(yz)$ orbitals for each superlattice (SL) and bulk. This includes charges from DFT, DFT + DMFT, and average orbital charge per layer (orb. ave.) for each SL and bulk.

the charge in the $xz(yz)$ orbitals, which appear to tend to half-filling (whereas the xy orbitals are tending towards zero charge). This is a likely consequence of these orbitals trying to reduce the potential energy, analogous to what is seen in the previous monolayer calculations.

Interestingly, the DFT averaged V Wannier orbital charge over all SrVO_3 layers for the decreasing number of SrVO_3 SLs is slightly (but noteworthy) lower than $\frac{1}{3}$ (the sum of all of these averaged Wannier t_{2g} orbitals is equal to ~ 1 , as expected). The Ti states have a small amount of charge, as shown in Table II. This table shows the DFT muffin tin (of each species) and interstitial charge percentages calculated from integrated DOS within the correlated energy windows (used for the DMFT calculations). The total charge equals the number of V atoms (which each contribute one valence electron) in the unit cell (i.e., for the 3:6 SL, the total charge in the correlated energy window is three). As can be seen in Table II, the Ti charge percentage contribution decreases with increasing number of SrVO_3 layers. The greatest contribution to the Ti charge is from the interface Ti [$3d_{xz(yz)}$ states], shown in Table II. The difference in the total and interface Ti contributions corresponds to the charge in the other SrTiO_3 layers, which is small compared with the interface Ti charge. Therefore, the charge is likely to be primarily leaking from

FIG. 12. Spectral functions of the 2:7 (top), 3:6 (middle), and 6:5 (bottom) superlattices (SLs) from fully charge self-consistent (FCSC) calculations, showing xy (left) and $xz(yz)$ (right) orbitals. The spectra of the insulating 2:7 SL have been shifted such that the Fermi level lies at the center of the band gap of the xy spectrum.

TABLE II. The DFT integrated DOS percentages (%) of the total charge within the correlated energy window. The charge per interface Ti atom is given to show how much charge has leaked to the Ti interface.

SL	Interstitial	Sr	V	O	Ti	Ti interface
2:7	19.1	0.6	66.6	10.8	2.9	2.7 (= 0.027 e-/Ti)
3:6	18.9	0.6	67.3	10.9	2.3	2.1 (= 0.0315 e-/Ti)
6:5	18.9	0.6	68.5	10.8	1.2	1.1 (= 0.033 e-/Ti)
Bulk	19.2	0.7	69.1	11.0	—	—

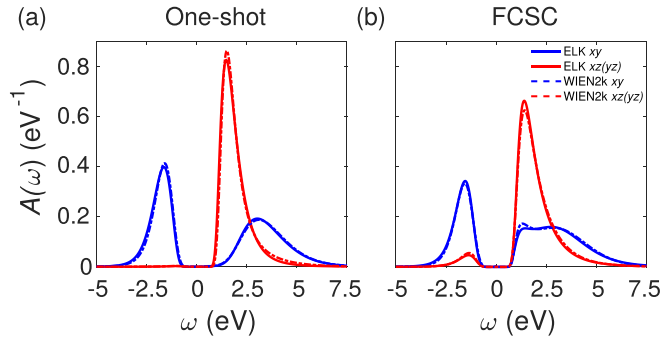

FIG. 14. The orbital $A(\omega)$ comparisons between the one-shot (OS) and fully charge self-consistent (FCSC) density functional theory (DFT) + dynamical mean-field theory (DMFT) methods from different input DFT codes for monolayer SrVO_3 .

the V to the interface Ti atoms (due to hybridization between the V t_{2g} and Ti t_{2g} at the interface), as indicated by the increasing V charge contribution with the number of SrVO_3 layers. However, the amount of charge on the (interface) Ti atoms is small and only a few percent of the total charge (consistent with the small DFT Wannier charge deviation in Fig. 13), which is quite small. For this reason, the Ti states were not treated within DMFT.

2. Effects of strain

We performed volume-conserving strain calculations on bulk SrVO_3 to investigate the effect CF has on the MIT while the bandwidths of the t_{2g} orbitals are approximately unchanged. Compressive strain of 1% was applied along the c axis; the other axes were tensively strained to conserve volume compared with the bulk. This strain was chosen to yield a CF splitting of 53 meV, slightly larger than but comparable with the CF splitting of the 2:7 SL. The strained FCSC U_{MIT} is ~ 6.525 eV, the same as for the bulk. The OS strained calculation had a slightly lower U_{MIT} of 6.475 eV. Due to the small change on U_{MIT} , the CF splitting is insufficient to cause the MIT in these SLs.

3. Comparing with the monolayer

The results presented used an in-house interface between ELK and TRIQS, so this section presents comparison results between ELK and WIEN2K inputs into TRIQS to show that the interface works for a similar system, namely, monolayer SrVO_3 . The monolayer SrVO_3 calculation was set up in the same way and using the same parameters as in Ref. [21]. Figure 14 shows the comparison between $A(\omega)$ calculated

FIG. 15. Comparison of the density functional theory (DFT) total density of states (DOS), one-shot (OS) GW (G0W0) total spectral function and the fully charge self-consistent (FCSC) DFT + dynamical mean-field theory (DMFT) Wannier V t_{2g} spectral function.

from the different DFT code inputs. This comparison shows excellent agreement between the different inputs for the different DFT + DMFT methods. This test shows that the interface used between ELK and TRIQS is able to reliably perform DFT + DMFT calculations.

To show that the insulating phase in these heterostructures is a strongly correlated effect, we performed a OS GW (G0W0) calculation on the free standing SrVO_3 monolayer within ELK to see if the insulating state can be obtained by including nonlocal exchange effects. The electron correlations in the monolayer (originating from dimensionality effects here) are expected to be the greatest out of all systems studied in this paper. The G0W0 calculation started from the converged monolayer DFT calculation and used a k -mesh of $15 \times 15 \times 1$, q -mesh of $5 \times 5 \times 1$, maximum Matsubara frequency cutoff of 272.11 eV, and $\beta = 7.74 \text{ eV}^{-1}$ (note this high temperature will notably smear the spectral function). Figure 15 shows that both DFT and G0W0 predict the system to be metallic, whereas the DFT + DMFT results are insulating, which is in line with the experimental results. The more subtle sharp features seen in the DFT have likely smeared out in G0W0, but the noisy features in the G0W0 spectral function are likely from the BZ integration (which did not use interpolation; BZ integrations with interpolation cannot be used with nonlocal quantities). The metallic G0W0 results show that the experimentally observed insulating state in the heterostructures is most likely due to the strong electron correlations, as described by DFT + DMFT.
